ABSTRACT

Acute renal failure is characterized by an abrupt decline in renal function resulting in an inability to excrete metabolic wastes and maintain proper fluid and electrolyte balance. The present study was undertaken to evaluate the serum electrolytes, glucose, protein, creatinine, urea, antioxidant enzymes and oxidant products in male acute renal failure patients. For the present study, 46 subjects of male acute renal failure aged 30 – 80 in year and 60 ages matched male healthy control were assessed. A significant (P<0.001) increase serum potassium, creatinine, urea, and plasma malondialdehyde levels were found in male acute renal failure group while serum sodium, protein, and antioxidant enzymes were found to be decreased significantly (P<0.001) when compared to male healthy control group. This review will also discuss diagnostic tools, strategies for improved design of clinical trials, and other therapeutic interventions that will be needed to properly treat acute renal failure in the 21st century.

Key words: Acute renal failure, Serum electrolytes, superoxide.
necrosis, but patients with acute renal failure due
to other causes might not\textsuperscript{15-17}. Acute renal failure
can result from decreased renal perfusion without
cellular injury; an ischemic, toxic, or obstructive
insult to the renal tubule; a tubulointerstitial process
with inflammation and edema; or a primary
reduction in the filtering capacity of the glomerulus.

Smoking was associated prospective with
increased risk for acute renal failure in the elderly\textsuperscript{18}.
Acute renal failure due to rhabdomyolysis from
substance misuse is increasing in human being.
Alcohol is frequently responsible\textsuperscript{19, 20}. Smoking may
also injure the kidneys by damaging the renal
microvascular through oxidative stress, reduced
nitric oxide generation, and increased plasma
endothelin concentration. Smoking-induced cell
dysfunction may further contribute to
tubulointerstitial injury\textsuperscript{21, 22}.

\textbf{MATERIAL AND METHODS}

The clinical material for present study
comprised 46 patients of male acute renal failure
admitted in medicine ward M. Y. Hospital, M. G. M.
Medical College, Indore (M. P.), India and 60 ages
matched male healthy control groups. The age
range was taken from 30 to 80 years. Blood
samples were collected from the patients at the time
of admission as well as from individuals of male
healthy control group. Clinical investigations were
performed in the Department of Medical
Biochemistry, M. G. M. Medical College, Indore (M.
P.), India. Serum protein (Total), creatinine, urea,
and superoxide dismutase were estimated by
biuret, jaffe's, diacetyl monoxime, and misra H P et
al methods respectively. Plasma malondialdehyde
and haemolsyate glutathione reductase,
glutathione peroxidase, and catalase, were
estimated by Jean C D et al method (1983), Horn H
D (1963), Hafeman D G method (1974), and Asror
K sinha method (1972) respectively. Serum
electrolytes were estimated by end-point kit method.
Obtained data were analyzed statistically by using
student "t" test.

\textbf{RESULTS}

1. We observed, highly significant (p<0.001)
increased biochemical values in the form of
serum potassium ions, creatinine, urea, and
plasma malondialdehyde when compared
to male healthy control groups (Table No. 1
and 2).

compared to age matched male healthy control groups (Table No. 1 and 2).
3. Table number three showing comparison male acute renal failure between age 30 – 50 and 51 – 80 years. Levels of sodium ions, superoxide dismutase, glutathione reductase, glutathione peroxidase, and catalase were decreased highly significantly (p<0.001) between aged 51 to 80 years of male acute renal failure and also highly significantly (p<0.001) increased levels of potassium ions, creatinine, urea and plasma malondialdehyde were observed in age range 51 – 80 years of male acute renal failure.

**DISCUSSION**

Amongst several diseases, that affect the human these days, acute renal failure is considered the most dreaded. Acute renal failure is defined as the loss of renal function over a period of hours to days, as reflected in the glomerular filtration rate. Acute renal failure is usually considered a disease of the hospitalized patients. Hypekalemia in acute renal failure is usually caused by decreased elimination by the kidney. Affects potassium excretion due to reduced nephron mass (number of functioning collecting ducts) and intrinsic impairment of active potassium secretion. Because the number of collecting ducts is directly related to the glomerular filtration rate, renal failure whether acute or chronic, leads to impaired renal potassium secretion. Increased levels of blood urea nitrogen (urea) indicated the presence of reversible vasoconstriction, while uncontrolled accumulation of nitrogen waste products i.e. blood urea and serum creatine indicated established acute renal failure.

Hyperglycemia is a known cause of enhanced plasma free radicals concentration. These are many ways by which hyperglycemia may increase the generation of free radicals. The term "auto-oxidation glycosylation" described the capability of glucose to analyze, there by reducing molecular oxygen and yielding oxidizing intermediates. The pathophysiology of hyperglycemia is characterized by changes in extracellular fluid volume and in effective osmolality. Many authors have reported incidence of hyponatremia was 19.69 percent in all renal failure patients, and defined as serum sodium 130 mEq / L. Nitrogenous waste products from protein metabolism are retained in the body, resulting in azotemia, as evidenced by the increased serum levels of urea nitrogen.

Oxidative stress is defined as an imbalance between formation of reactive oxygen species and antioxidative defence mechanism. Reactive oxygen species can damage protein, carbohydrate, and nucleic acids. Unlike complete reduction, incomplete reduction of molecular oxygen of free radical formation. It is estimated that 1 to 3 per cent of oxygen consume by cells are channeled into the generation of reactive oxygen species. Reactive oxygen species are intermediary metabolites that are normally produced in the course of oxygen metabolism. The oxidative-antioxidative system imbalance leads to the pathology called oxidative stress. Acute renal failure can be triggered or aggravated by reactive oxygen species but established acute renal failure per se might also affect the antioxidant defense mechanisms of the organism. The role of reactive oxygen species in ischemic acute renal failure remains in question. Some studies in animals show that antioxidants or scavengers of reactive oxygen species protect against functional tissue damage whereas other studies do not.

Among the defence system operating against the reactive oxygen species, superoxide dismutase, glutathione peroxidase, and catalase are the most important antioxidant enzymes (AOEs). The glutathione peroxidase / glutathione system may be important in low-level oxidative stress. Catalase is an intracellular antioxidant enzyme that is mainly located in cellular peroxisomes and to some extent in the cytosol, which catalyzes the reaction of hydrogen peroxide to water molecular oxygen. Catalase is very effective in high-level oxidative stress and protects cells from hydrogen peroxide produced within the cell. Superoxide dismutase is generally thought to play a central role because it scavenges superoxide anion at the initial step of the radical chain reaction.
Malondialdehyde, a secondary breakdown product of fatty acid peroxide, is a highly reactive substance, and even in physiological concentration it can react with erythrocyte membrane phospholipids, cross-linking their polar heads. When modified by malondialdehyde, red blood cells lose their normal cationic gradient and show reduced deformability in vitro, in addition to a significantly shortened life span in vivo. Oxidative stress occurs when there is an excessive free radical production and low antioxidant defence and results in chemical alteration of biomolecules which cause structural and functional modifications. Polysaturated fatty acids are oxidized in vivo by free radicals and other species. Degradation of oxidized lipid molecules leads to the formation of malondialdehyde in excess.

Therefore, the present study on patients of acute renal failure of different age groups in male sexes makes us conclude that if the estimation of serum sodium, potassium, protein (Total), creatinine, urea, antioxidant enzymes, and oxidant product are done in the newly diagnosed cases may be suggestive for early phase of disease. Oxidative stress in elderly patients intensified especially if the patients have associated with renal complications especially in middle age. This can forewarn the patients for prophylactic measures as would be suggested by the treating physician.
