ABSTRACT

Inverted papillomas comprises 0.5-4% of benign epithelial nasal tumors that arise primarily from the lateral nasal wall. The main characteristic is its tendency to recur and the risk of malignant transformation. The present study aims to analyze and report the findings of our team in the treatment of these lesions, especially through the endoscopic approach and the outcomes of the patients. This is a retrospective study describing 38 patients who underwent endoscopic excision or open surgery from March 2001 to March 2012. The patients were studied by age, sex, origin of lesion, presenting symptoms, radiological studies, clinical staging, method of treatment, follow up, surgical outcome, tumor recurrence and associated malignancy. The mean follow-up was 48 months. There were 30 men and 8 women with the mean age of 49.76 years ranging 18 to 78 years old. The most common clinical symptoms were unilateral nasal obstruction (94.7 %) and rhinorrhea (36.84 %). Disease recurrence rate was 5.3 %. Endonasal endoscopic resection was performed in 32 patients (84.2%), combined approaches were used for 5 patients (13.2%) and external approach only was done in one patient. The most common involvement location was the maxillary sinus (89 %). The ethmoid sinus and the lateral nasal wall were involved in 68% and 55.2% of the cases, respectively. Malignant transformation was observed in 2 patients (5.3 %). Long-term follow up of inverted papilloma is necessary for early detection of recurrence and to allow for surgical salvage. Surgeon's experience plays a crucial role in the selection of an appropriate method.

Key words: inverted papilloma, endoscopic surgery, open surgery, outcome

INTRODUCTION

Inverted papilloma is a benign sinonasal epithelial neoplasm which involves the lateral nasal wall. It comprises 0.5 – 4 % of primary nasal neoplasms, its peak age is the 5th or 6th decade of patients' life and involves men more than women1. Clinical symptoms depend on the involvement location but the most common symptom is unilateral and progressive nasal obstruction. Other symptoms usually include unilateral sinonasal discharge but bilateral sinonasal involvement is reported in 1 – 9 % of the cases2, 3, 4. A pink, polypoid, smooth or lobulated papillary mass seen in the lateral nasal wall above the inferior turbinate in the nasal cavity during examination is indicative of inverted papilloma that can be differentiated from antrochoanal polyp or other neoplastic lesions5. Lateral rhinotomy and medial maxillectomy were selected as surgery methods in the past for the treatment of inverted papilloma. Endoscopic surgery is another method which was seriously proposed during the last decade. Its advantages include avoiding external incisions, maintaining the normal physiological function of the mucociliary system and the possibility of regular endoscopic examinations during post-surgery follow-ups6. Surgeons' views on the priority of surgical methods
are different. Several studies have indicated that
the recurrence rate of endoscopic surgery is 3 – 17%
which is less than the recurrence rate of external
surgery (7). The highest neoplasm recurrence rate
is early recurrence at its primary location and its
most important cause is incomplete removal of the
neoplasm. This is why some surgeons prefer the
external rhinotomy method over the endoscopic
method. Therefore, the present study investigates
the results and outcome of endoscopic surgery in
patients with inverted papilloma administered in
Imam Khomeini and Apadana Hospitals (Ahvaz,
Iran) between 2001 and 2012.

MATERIALS AND METHODS

This retrospective study was conducted
on 38 patients. Demographic information and
medical records of the patients from 21st March
2001 to 19th March 2012 along with their pathology
results were collected and were pursued for
recurrence using sinonasal endoscopy and
computer imaging of the sinuses. Their
demographic information including age at
diagnosis, gender, as well as their symptoms,
location of neoplasm after diagnosis, surgery type
(Endoscopic surgery, lateral rhinotomy and
Caldwell-Luc surgery) were extracted. They were
called and invited for a revisit and endoscopy to be
checked for the recurrence of symptoms.
Descriptive statistics and chi-square test were used
for providing frequency tables and indices and
comparing recurrence rates, respectively.

RESULTS

Among 38 patients in the study, 30 were
male (78.9 %) and 8 were female (21.1 %). The
male – female ratio was 3.75:1. The mean age of
the patients was 49.76 years with the age range of
18–78 years old at the time of symptoms diagnosis
(Figure 2). The most common symptom was
unilateral nasal obstruction (94.7%). The other
symptoms included nasal discharge and postnasal
drip (36.84 %), headache (13.15 %), nasal bleeding
and loss of the sense of smell (the prevalence of
10.5 % for each) and voice change (2.6 %).

The sinonasal involvement was mostly
unilateral. In 42.1 %, 47.4 % and 10.5 % of the
cases involvement was at the right and left and
bilateral, respectively. The most common
involvement location was the nasal cavity (89%),
The maxillary sinus (68 %), ethmoid sinus (55.2
%), the frontal sinus(26.3%), the sphenoid sinus
(23.6 %) and nasopharynx (15.87%) were the most
common after the maxillary sinus. According to the
Krouse classification, 7.89 %, 39.47 %, 26.31 %
and 26.31 % of patients were in T1, T2, T3 and T4
classes, respectively at diagnosis. Moreover, 32
(84.2%), 5(13.2%) and 1 patients underwent
endoscopic surgery, endoscopic with Caldwell-Luc
surgery and lateral rhinotomy surgery, respectively.
Among 38 studied patients, 6 (15.8%) underwent
surgery after early diagnosis of polyposis during
endoscopic examination and imaging whose side
was determined in the pathological diagnosis of
sinonasal inverted papilloma.

During follow-up, two patients with
squamous carcinoma (5.3 %), were observed that
one case was metachronous and one synchronous
with the diagnosis of inverted papilloma. This patient
was a 52-year-old man who had visited with nasal
obstruction symptoms and nasal mass at the right.
His involved sinuses were maxillary, ethmoid,
frontal and sphenoid sinuses. Erosion of lamina
papyracea was observed in this patient during an
endoscopy surgery. He undergone endoscopy
surgery and severe localized dysplasia (in situ
carcinoma) was reported in his pathology (fig 1).
After 36 months of follow up, no evidence of
recurrence was observed in the patient . He was
diagnosed with synchronous squamous carcinoma
along with sinonasal inverted papilloma. The
second patient was a 73-year-old man who
underwent surgery with nasal obstruction. Bleeding
from the right nasal cavity and sinonasal inverted
papilloma were reported in his pathology.
eightmonths after the surgery, symptoms recurred
at the the same side. After endoscopy surgery and
histopathological examination of the sample, the
diagnosis of inverted papilloma along with well-
differentiated squamous carcinoma was
confirmed, the patient was underwent open surgery.

We had recurrence of two cases and
isolated frontal sinus involvement was observed in
one case. The patient had nasal obstruction and
discharge with swelling of the left upper eyelid. The
involvement of the frontal sinus with expansion into orbit and chronic polyposis was observed and the patient underwent surgery with the diagnosis of frontal sinus mucocele with expansion to the left orbit. Periorbital abscess, polyposis, chronic sinusitis and sinonasal inverted papilloma was reported in his pathology. This patient had a history of 3 surgeries due to polyposis and inverted papilloma was not reported in any of pathology results.

There was no significant relationship between recurrence rate and patient age and gender based on Fisher's exact statistical test (p: 0.999). Recurrence rate was 12.5 % and 16.7 % in women and men, respectively.

**DISCUSSION**

Inverted papilloma is a type of sinonasal neoplasm which can occur at any age. However, the majority of patients are affected during the 5th and 6th decade of their life. This neoplasm is more common among men. Its main characteristic is its tendency to recur and its remodeling and bone destruction ability. Although it is primarily benign, its malignant transformation is well-recognized. Clinical symptoms of inverted papilloma are different depending on the extent of involvement of surrounding structures and the presence of secondary pathology. Unilateral nasal obstruction has been the most common clinical symptom in most studies.

In the past, choice of treatment for patients with sinonasal inverted papilloma was open surgery, but Nowadays, most articles support the endoscopic method as the selected method for the treatment of these patients. The indication of endoscopic surgery is more widespread today and larger neoplasms can be successfully operated with this technique. External surgery methods are conducted on certain patients in combination with endoscopy in recent years. In today's world in which surgery and hospitalization duration are two important conditions in surgical planning, endoscopic medial maxillectomy is very useful. Recurrence rate in external surgery methods for sinonasal inverted papilloma varies from 0 – 36 % while this rate is 0 – 25 % for endoscopic surgery methods.

It is important that endoscopic surgery of neoplasms depends on the technique and is associated with potential complications. In order to ensure low recurrence rate and avoid complications, endoscopic resection of the neoplasm should be done by skilled and experienced surgeons using endoscopic sinus surgery techniques.
Moreover, the role of endoscopy is important in patient pursue. Careful observation of sinonasal cavity after surgery using endoscope results in early diagnosis of the disease and its recurrence\textsuperscript{11, 15}. Furthermore, long-term examination is recommended since it can recur after years. Recurrent inverted papilloma is associated with the risk of squamous carcinoma and its rate is reported to be 2 – 53%. With respect to the possibility of secondary malignant transformation, long-term follow up of patients with nasal endoscopic methods and if required, CT scan and MRI is necessary\textsuperscript{15, 16}. Imaging plays an important role in patient evaluation. It determines the extension of the neoplasm and bone erosion or invasion of surrounding structures such as skull base and orbit. These changes can predict associated malignancy and change the type of treatment. Although CT scan can determine the method of inverted papilloma surgery, MRI can reveal neoplasm spread more accurately by differentiating it from remaining discharge and associated sinusitis\textsuperscript{12}.

The majority of this study’s patients were male (78.9 %) which is consistent with the majority of studies\textsuperscript{9, 12, 13}. Patients ranged 18 – 78 years old and they were 49.76 years old on average when symptoms were diagnosed which is consistent with other studies\textsuperscript{8, 9, 12}. The male – female ratio was 3.75:1 in this study. In a study by De susa\textit{et al.}, this ratio is reported 1:1\textsuperscript{11} which is inconsistent with the present study. Moreover, in a study by Baradaran far \textit{et al.} in Yazd, male – female ratio is reportedly 11:1\textsuperscript{12} which is inconsistent with the present study. The most common clinical symptom in this study was unilateral nasal obstruction (94.7 %) which is consistent with the majority of studies\textsuperscript{9, 11, 12, 13}. The involvement location in this study was mostly unilateral which was more common on the left. In 10.5 % of patients, the involvement was bilateral which is inconsistent with the results of a study by Bhandary \textit{et al.}\textsuperscript{13}. The present study is consistent with a study by De susa \textit{et al.} in which 11.5 % of patients suffered from bilateral sinonasal involvement but the most common involved location was at the right\textsuperscript{11}. In the study by Baradaranfar, involvement was more common on the left and 12.5 % of patients had bilateral sinonasal involvement\textsuperscript{12}. The most common involved sinus in this study was the maxillary sinus. This issue has been studied in other studies too\textsuperscript{10, 11}. In a study by P. Diaz Molina, the most common involved sinus was the ethmoid sinus\textsuperscript{10}. Other involved sinuses in this study include ethmoid, frontal and sphenoid sinuses in the order of their prevalence. This result is rather inconsistent with the one by De Susa in which the least common involved sinus was the frontal sinus\textsuperscript{11}.

Recurrence rate during this study was 5.3 % (2 patients) but no recurrence was observed during some studies\textsuperscript{13}. This result is inconsistent with the one by the present study. In some studies, recurrence rate was reportedly 7.1 %\textsuperscript{10, 12}. This rate was higher in some studies at about 25 %\textsuperscript{11} which is inconsistent with the present study. Two cases of malignancy associated with inverted papilloma were observed during this study. Once case was in situ synchronous carcinoma and the other one was metachronous squamous carcinoma which occurred 8 months after the primary inverted papilloma diagnosis. No evidence of symptoms was observed during the study 36 and 19 months after the diagnosis of carcinoma. In a study by Bhandary\textit{et al.}, 10.7 % of malignancy was observed with inverted papilloma and all 3 cases were squamous carcinoma\textsuperscript{12} which was consistent with the present study.

In another study by Kim \textit{et al.}, malignancy rate with inverted papilloma is reportedly 7 %. These patients did not have a significant age difference at diagnosis with other patients with inverted papilloma in that group. One of these malignancies was transitional carcinoma and other were squamous carcinoma, most of which were reported to be synchronous (9). In another study by P. Diaz Molina, 16 % of patients suffered malignancy along with inverted papilloma. Most of the cases were squamous cell carcinoma and 2 were transitional carcinoma most of which were synchronous\textsuperscript{10}.

**CONCLUSION**

Today, endoscopic approaches tend to be the choice for treatment of the majority of inverted papillomas. The close follow up of the patient for a long period of time is necessary for early detection of recurrence and to allow for surgical salvage. Surgeon’s experience is a determining factor when choosing the type of surgery for these cases.
